METHODS

Sample collection

The following procedure was developed for the isolation of eicosanoids from six-well cell culture plates containing 2.0 ml of media. We have also adapted this method to other sample types and sample volumes by scaling our procedure as needed. The media was removed and 100 μ l of a mixture of internal standards (containing 10 ng/100 μ l of each standard in EtOH) was added followed by 100 μ l of EtOH to bring the total concentration of EtOH to 10% by volume. Samples were centrifuged for 5 min at 3000 rpm to remove cellular debris. The eicosanoids were then isolated via solid-phase extraction. When intracellular eicosanoids were analysed, adherent cells were scraped into 500 μ l of MeOH, and then 1000 μ l of phosphate-buffered saline (PBS) and 100 μ l of internal standards were added. Scraping cells in aqueous solutions was shown to activate eicosanoid production, whereas doing so in MeOH effectively stopped the reactions and lysed the cells. These samples were then processed the same as the media.

Eicosanoid isolation

Eicosanoids were extracted using Strata® X SPE columns (Phenomenex, Torrance, CA). Columns were washed with 2 ml of MeOH followed by 2 ml of H₂O. After applying the sample, the columns were washed with 1 ml of 10% MeOH, and the eicosanoids were then eluted with 1 ml of MeOH. The eluant was dried under vacuum and redissolved in 100 μ l of solvent A (water-acetonitrile-formic acid [63:37:0.02; v/v/v]) for LC-MS/MS analysis.

Reverse-phase liquid chromatography

The analysis of eicosanoids was performed by LC-MS/MS. Eicosanoids were separated by reverse-phase LC on a C18 column (2.1 \times 250 mm; Grace-Vydac, Deerfield, IL) at a flow rate of 300 μ l/min at 25°. All samples were loaded via a Pal auto-sampler (Leap Technologies, Carrboro, NC) that maintained the samples at 4° to minimize degradation of eicosanoids while queued for analysis. The column was equilibrated in Solvent A, and samples (dissolved in Solvent A) were injected using a 50- μ l injection loop and eluted with a linear gradient from 0 to 20% solvent B (acetonitrile-isopropyl alcohol [50:50; v/v]) between 0 and 6 min; solvent B was increased to 55% from 6 to 6.5 min and held until 10 min; solvent B was increased to 100% from 10 to 12 min and held until 13 min; and then, solvent B was dropped to 0% by 13.5 min and held until 16 min.

Chiral chromatography

When it was required to isolate isomeric eicosanoids, normal-phase chiral liquid chromatography was carried out using the same pumping system described above for reverse-phase chromatography. Separation was carried out on a 4.6 \times 250 mm Chiral Technologies (West Chester, PA) derivatized amylose column (Chiralpak® AD-H) equipped with a guard column (Chiralpak® AD-H guard column) held at 35°. Buffer A was hexane/anhydrous ethanol/water/formic acid: 96/4/0.08/0.02, v/v; buffer B was 100% anhydrous ethanol. This small amount of water in buffer A is miscible in the hexane/anhydrous ethanol mix and was found to be vital for satisfactory chiral separation and peak shape. Gradient elution was achieved using 100/0: A/B at 0 min; linearly ramped to 90/10: A/B by 13 min; linearly ramped to 75/25: A/B by 15 min and held until 25 min; and then linearly ramped back to

100/0: A:B by 27 min and held there until 42 min to achieve column re-equilibration. The chiral chromatography effluent was coupled to a mass spectrometer for further analysis.

Mass spectrometry

All MS analyses were performed using an Applied Biosystems (Foster City, CA) 4000 QTRAP hybrid, triple-quadrupole, linear ion trap mass spectrometer equipped with a Turbo V ion source and operated in MRM mode. For all experiments, the Turbo V ion source was operated in negative electrospray mode (chiral chromatography utilized the ion source in chemical ionization mode, as shown later) and the QTRAP was set as follows: CUR = 10 psi, GS1 = 30 psi, GS2 = 30 psi, IS = -4500 V, CAD = HIGH, TEM = 525°, ihe = ON, EP = -10 V, and CXP = -10 V. The voltage used for CID (-15 to -35 V) and the declustering potentials (-30 to -100 V) varied according to molecular species and were maximized for each eicosanoid. The Turbo V ion source was operated in atmospheric pressure chemical ionization (APCI) mode when employing chiral chromatography using the following settings: CUR = 10 psi, GS1 = 45 psi, GS2 = 60 psi, NC = -3.0 μ A, CAD = HIGH, TEM = 400°, ihe = ON, DP = -60 V, EP = -15 V, and CXP = -10 V.

Quantitation

Eicosanoid quantitation was performed by the stable isotope dilution method previously described by Hall and Murphy (Hall and Murphy, 1998). For each eicosanoid to be quantitated, an internal standard was selected that had a different precursor ion mass than the target analyte but was chemically and structurally similar to the target analyte as possible. This is ideally achieved by using a deuterated analogue of the analyte. We employed these standards whenever they were commercially available. In other cases, we employed a deuterated analogue that was the closest to the desired analogue in characteristics. For example, 15d- Δ 12,14 PGJ2 (d4) was employed as the internal standard for PGJ2, 15d- Δ 12,14 PGJ2, and 15d- Δ 12,14 PGD2. Table 3.1 lists the internal standards that we are currently employing (boxes in grey) and indicates which internal standard is used with which analyte. Presently, eight deuterated internal standards are used to quantitate 16 eicosanoids. An aliquot of the internal standard (10 ng std/100 μ l of ethanol) was added to either the media or cell extracts immediately following its isolation. The samples were then processed as previously detailed.

The primary standards contained an accurately known amount of each eicosanoid (non-deuterated) to be quantitated and an accurate aliquot of the internal standards. The concentration of the primary standards must be known with high accuracy. This can be accomplished in one of several ways. In some cases, they are commercially available. Cayman Chemicals, for example, offers a "Quanta-PAK" version of many eicosanoids that contains a deuterated internal standard and a vial containing an accurately determined amount of the non-deuterated primary standard. Some of the eicosanoids (e.g., some HETEs and leukotrienes) have significant ultraviolet (UV) absorption that can be employed to determine the concentration of the standard. The amount of standard can also be determined gravimetrically if a microbalance is available.

The set of primary standards was then prepared by adding accurately determined amounts of the given analyte (non-deuterated) to 100 μ l of the same internal standard used to spike the samples. (Note: the concentration of the internal standard does not need to be accurate, but it is crucial that an accurately known volume of the exact same internal standard is added to the sample and to the primary standards.) A typical standard curve consisted of 0.3, 1, 3, 10, 30, and 100 ng of primary standard per 100 μ l of internal standard containing 10 ng of each internal standard. The internal standard and the primary standard samples were run before and after each set of unknown samples, and 10 μ l of each was loaded onto the column.

A linear standard curve was generated where the ratio of analyte standard peak area to internal standard peak area in the primary standards was plotted versus the amount of primary standard (ng). Figure 3.1 shows examples of three typical standard curves. Linear regression analysis was used to calculate the slope and intercept of the standard curves that were then used to calculate the unknowns. R² values for these curves of greater than 0.99 were routinely obtained. The ratio of the unknown analyte peak area to internal standard peak area in the sample was then compared to the appropriate standard curve to calculate the amount of analyte in the sample. Since, in some cases, the deuterated standards contained a small percent of non-deuterated analyte, the LC-MS/MS of the internal standard was analysed to determine the amount of non-deuterated analyte present. In this case, the non-deuterated contaminant was subtracted from each analysis. The dynamic range that can be covered is limited on

the low end by the amount of non-deuterated analyte in the internal standards and the sensitivity of the mass spectrometer. The upper limit is restricted by ion suppression and detector saturation issues.

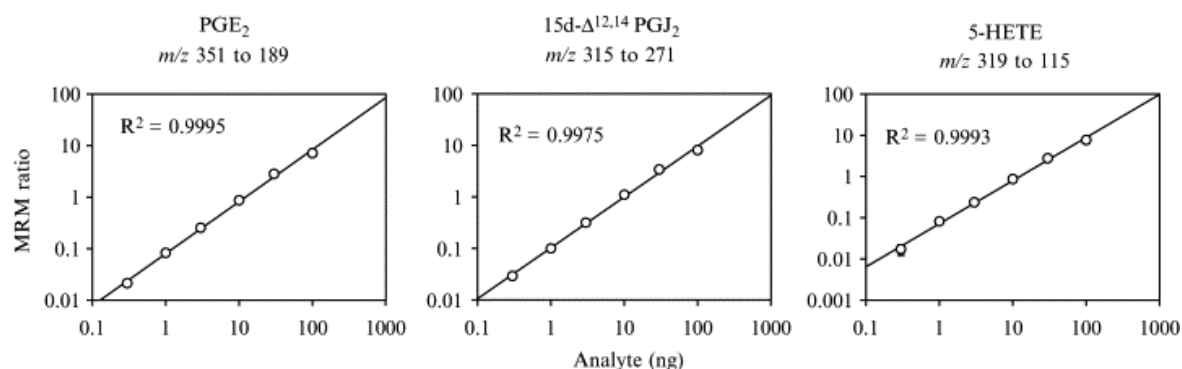

Figure 3.1. Eicosanoid standard curves. Three typical standard curves are shown. The standard solutions are prepared as described in the “Methods” section. The solutions contained 10 ng of an internal standard for each analyte and 0.3 to 100 ng of the analyte in 140 μ l of which 10 μ l were analysed. The multi-reaction monitoring (MRM) transitions employed to monitor the analytes are listed in the figure. The internal standards and transitions were: PGE₂ (d4) m/z 355–193, 15d- $\Delta^{12,14}$ PGJ₂ (d4) m/z 319–275, and 5-HETEs (d8) m/z 327–116. The data were presented in log scale, but the linear regression analysis to determine parameters was done on the original non-log data.

MRM transition selection

To date, we have compiled a library of over 60 eicosanoids that we can detect and quantitate with these methods. These compounds are listed in Table 3.1 with the precursor and product ions used in the MRM analysis. We have also included in this table several compounds for which we have MS/MS spectra but for which we have not selected MRM transitions. We have not included any recovery or limit of detection data for these compounds. We have compiled the MS/MS spectra of each of these compounds. We have published these data (Harkewicz et al., 2007). These data also can be accessed on the LIPID MAPS web page at <http://www.lipidmaps.org>. In addition to MS/MS spectra, the web visitor can obtain chemical structures for standards in both GIF and ChemDraw® formats, specific details regarding LC and MS parameters employed in our analysis, structures of dominant fragment ions (including literature references, when available, for fragment assignments), and retention times for a stated set of chromatographic conditions. Lastly, a web link to Cayman Chemical provides useful information and references on specific eicosanoids.

The product ions employed here for the MRM detection were selected to yield the best discrimination from other eicosanoids that co-elute in the vicinity of the analyte and to yield the highest signal. By balancing LC retention time and product ion selection, we were able to successfully distinguish the large majority of the eicosanoids listed. Various product ions can be selected to obtain greater sensitivity if conflicting eicosanoids are not present in a given set of samples. The MS/MS spectra of most eicosanoids show numerous product ions. While a similar eicosanoid may have the same product ions, their relative intensities usually vary. The ratio of intensities of these product ions can be used to distinguish these species. In this case, multiple MRM transitions can then be analysed, and the ratio of product ions found in the unknown can be compared with either an MS/MS library spectra or a pure standard run under the same conditions. This would aid in confirming the identity of a chromatographic peak. Figure 3.2 shows the chromatograms of a few selected eicosanoids to illustrate several points about this procedure. All of the panels in Fig. 3.2 were generated by overlaying the individual MRM chromatograms for the various MRM pairs onto a single plot.

The sharpest peaks have a width at half height of 6 s and the baseline peak width on the order of 18 s. The Applied Biosystems 4000 QTrap can handle over 100 MRM pairs in a single scan. The dwell time employed when we are scanning 60 to 70 analytes is 25 ms. This produces a cycle time of 2 s per scan. This translates to at least nine data points per peak for the narrowest peaks, which is sufficient to accurately define the peak shape for quantitation. The Applied Biosystems 4000 QTrap software allows the user to break the MRM pairs into sets, and these sets can be run in series during the course of a single analysis so that only a fraction of the MRM pairs are being

scanned during any time period. Running fewer MRM pairs in each scan allows the dwell time to be increased. Although this would not increase the absolute intensity of the peaks, it would increase the time averaging for each data point, thus decreasing the noise levels and increasing the signal-to-noise (S/N) ratio.

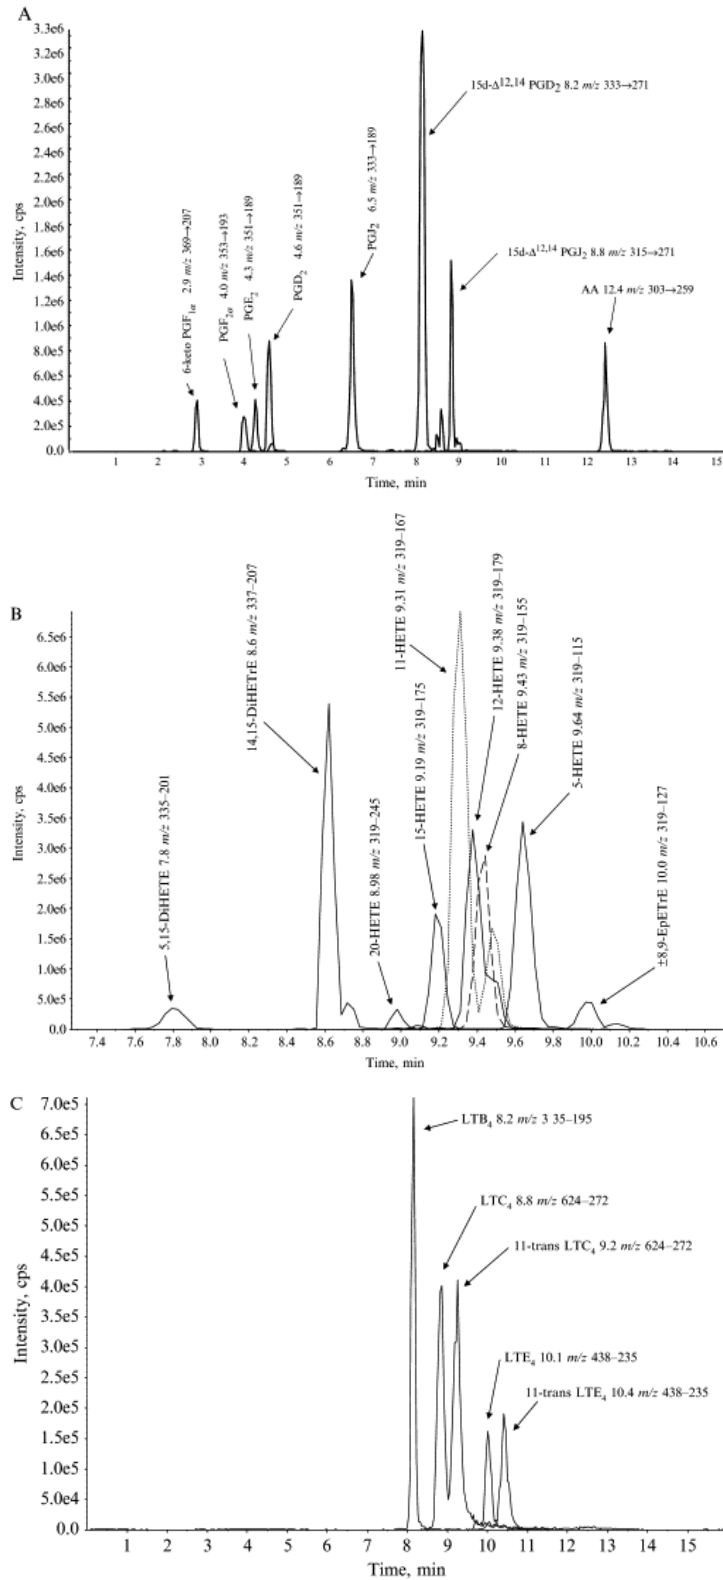

Figure 3.2. High performance liquid chromatography (HPLC) eicosanoid chromatography on reverse-phase C18. The chromatography profiles of selected eicosanoid standards run on reverse-phase C18 HPLC (see “Methods” section). In each panel, the individual chromatograms produced by a given multi-reaction monitoring (MRM) pair have been overlaid. Each label lists the eicosanoid, retention time, and multi-reaction monitoring transition that

produced a given chromatogram. (A) Representative sample of prostaglandins and arachidonic acid (AA). (B) Representative sample of the hydroxy-eicosanoids, including examples of HETEs, diHETEs, diHETrEs, and EpETrEs. (C) Representative sample of leukotrienes

Stereoisomer detection

Table 3.1 contains eight pairs of isomers that have identical retention time and MS/MS spectra, and thus cannot be distinguished with the C18 column. To identify and quantitate these isomers normal phase chiral chromatography is required.

Lower limit of detection

Table 3.1 also contains an estimate of the lower limit of detection (LOD) for the eicosanoid when employing our standard procedures. A set of standards was made and then serially diluted to produce a set of standards such that 1 to 5000 pg would be loaded onto the column. A signal was judged to be significant if the signal area was three times the noise at the three-standard-deviation level. Most limits were between 1 and 50 pg loaded onto the column. Only PGE2-EA had an LOD greater than 50 ng. The detection limits that we obtained were achieved with a 2.1×250 mm Grace-Vydac reverse-phase C18 column with 5 μ m particle size. Decreasing the column diameter, the particle size, and the flow rate can increase sensitivity, as can changing the column packing. We have analysed only one isomer of any isomeric analytes and only non-deuterated analytes. Therefore, we have listed the LOD and recovery values for the other isomers and for the deuterated standards as not determined (ND) in Table 3.1. However, their recoveries and LODs should be very similar to the corresponding isomer that was analysed or the equivalent non-deuterated analyte. Figure 3.3 shows an example of the analysis of a sample that was close to our lower limit of detection. It is the chromatogram showing the analysis of PGE2 and PGD2 in a sample of spinal fluid from a rat that had been subjected to the carrageenan model of inflammatory pain. This represents 52 pg of PGE2 load onto the column and correlates with 150 pg of PGE2 present in the original 42- μ l spinal fluid sample.

Figure 3.3. PGE2 analysis of rat spinal fluid. Spinal fluid was collected from a rat whose paw had been injected with carrageenan to induce an inflammatory pain state. A sample of spinal fluid was removed (42 μ l), processed as described in the “Methods” section and analysed by liquid chromatography–mass spectrometry–mass spectrometry. Eighty percent of the sample was analysed. The PGE2 peak corresponds to 52 pg of PGE2 being loaded onto the column. The signal-to-noise (S/N) ratio was 16-fold over a three-standard-deviation noise level.

Recoveries

Our primary goal was to analyze as many eicosanoids in a single run as possible. We chose to focus on maximizing the recovery of AA, prostaglandins, and HETEs. Table 3.1 shows the recoveries that this system achieved for most of the analytes that we detect. These recoveries were determined by adding a known amount of each analyte, contained in a standard mix, to 2.0 ml of water or DMEM, and then isolating the eicosanoids via the standard sample preparation method previously outlined. We also did an “add back” experiment where DMEM alone was extracted by the same method; however, instead of adding an aliquot of the standard eicosanoid mixture to the DMEM sample before extraction, the eicosanoids were added to the post-extraction methanol column effluent. Losses in the “add back” samples would indicate that materials in the media are being co-extracted with the eicosanoids, and that these contaminants affect the eicosanoid MS response. All three sets of samples were analysed with our LC-MS/MS procedure. The eicosanoid peak intensities of these samples were compared to those of standards that had not been through the isolation procedure, but instead were directly analysed by LC-MS/MS.

Table 3.1 reports the relative recoveries of standards that were extracted from DMEM. The mono- and di-hydroxy eicosanoids had excellent recoveries at between 75 and 100%. The leukotrienes and prostaglandins had only moderate recoveries in the range of 50%. In most cases, the recoveries of these compounds from water were in the 80 to 100% range. The “add back” experiment showed that, for the prostaglandins, most of the losses occurred in the “add back” experiment, implying that some component from the media is being extracted that decreases the MS response to the prostaglandins. However, the “add back” levels for the cysteinyl leukotrienes were 100% within experimental error, suggesting that the losses occurred during the extraction process, and that media components are not affecting leukotriene detection. Tetranor PGEM and PGFM do not bind to the Strata-X SPE columns under these conditions and could not be detected by this protocol. The PGK2 had very large errors, and extraction could not be measured. Again, the yield of a given class of compounds could be improved by altering the conditions or column type, but often at the expense of other analytes.

IMPORTANT NOTES

The process of culturing cells can affect the eicosanoid levels in other ways as well. For example, PGD2 can undergo dehydration to form PGJ2, 15d- Δ 12,14 PGJ2, and 15d- Δ 12,14 PGD2. This dehydration has been reported to be accelerated in serum albumin (Fitzpatrick 1983, Maxey 2000). This decomposition will not be compensated for by the internal standards since they are not added until after the cell incubations. We have also found that when 10% serum is present during the cell culture, no LTC4 could be detected; however, LTE4, which is a breakdown product of LTC4, was detected. When the same experiments are run in serum-free media, significant levels of the LTC4 were detected, but very little LTE4. Presumably, the serum is catalyzing the conversion of LTC4 to LTE4. Clearly, the types of recovery experiments outlined above must be conducted whenever applying this system to a new type of sample (e.g. media, serum, or tissues) or when changing the conditions of an already-tested sample. Care must also be taken to determine the effects that the addition of any agents (e.g., inhibitors, activators, or drugs) have on the extractions and on the quantitation of any other analytes. LC-MS/MS should also be done on the agents being added to determine if they have any MRM transitions that could be mistaken for one of the standard analytes.

Traditionally, lipids solutions were routinely acidified before subjecting them to liquid extractions. We compared our recoveries with and without acidifying the media before application to the SPE columns. We found that there were no significant differences; therefore, we do not routinely acidify the media. It is possible that eicosanoids other than those we employed in our testing could benefit by acidification. In addition, some eicosanoid species are susceptible to air oxidation and/or adhere to vessels and should not be taken to dryness. To guard against these losses, 20 μ l of a 50/50 solution of glycerol/ethanol can be added to the methanol column elution just before drying down the samples on the Speedvac. The glycerol remains, and the eicosanoids are concentrated into the glycerol, which can then be taken up in the LC equilibration buffer for LC-MS/MS analysis.

Table 3.1. Eicosanoid library

Eicosanoid	Systematic name	[M-H] (m/z)	Production (m/z)	LC retention time (min)	Internal standard	Recovery ^c	Limit of detection (pg on column)

- a Gray boxes indicate internal standards.
- b The retention times are given to indicate the relative elution position of the compounds with the understanding that the absolute values are not significant.
- c Recoveries were grouped as P for poor (<25%), M for moderate (25–75%), E for excellent (>76%), and ND for not determined.
- d These compounds were not analyzed quantitatively for this table, but the MS/MS spectra and LC retention times are available in the LIPID MAPS Eicosanoid Library at www.lipidmaps.org or in Harkewicz et al., 2007.
- e Tetranor PGFM and tetranor PGEM did not bind to the Strata-X SPE column and thus could not be detected by this method.
